Standard Errors with Antithetic Sampling

Nicholas R. Kirchner

March 3, 2013

1 Introduction

There was a discussion as to whether to divide by N (the number of pairs generated) or 2N (the total number of values) when computing the standard error of a quantity estimated through antithetic variance reduction. From a theoretical perspective, the correct answer differs from both of these.

In fact, if the two values x_i and x'_i generated via antithetic sampling are negatively correlated, this method turns out to be even more powerful than dividing by 2N from the perspective of reducing standard error.

The reason for the reduced standard error is that the covariance between the two values should be added before division by 2N, and therefore a negative covariance results in a lowered standard error.

From a computational perspective, it is not necessary to compute any covariances. Rather, it is easiest to simply make a list of the quantities $\frac{x_i + x_i'}{2}$ and compute the mean and standard error of that list.

2 Properties of Variance

If X and Y are random variables and a a constant, we have the following properties:

$$Var(aX) = a^2 Var(X)$$

$$Var(X + Y) = Var(X) + Var(Y) + 2Cov(X, Y)$$

In particular, when X and Y are independent we have Cov(X,Y) = 0, so

$$Var(X + Y) = Var(X) + Var(Y)$$

3 The Usual Case

First, back to basics. Our usual mean estimator is

$$\hat{\mu} = \frac{1}{N} \sum_{i=1}^{N} x_i$$

where N is the number of data points, and the x_i are the data points drawn from random variables X_i . If we presume that the X_i are I.I.D. (independent and identically distributed), we can calculate

$$Var(\hat{\mu}) = Var\left(\frac{1}{N}\sum_{i=1}^{N} X_i\right)$$
$$= \frac{1}{N^2} Var\left(\sum_{i=1}^{N} X_i\right)$$

Here's where independence comes in: we needn't worry about covariance.

$$= \frac{1}{N^2} \sum_{i=1}^{N} \operatorname{Var}(X_i)$$
$$= \frac{1}{N} \operatorname{Var}(X_i)$$

Taking a square root yields the standard error.

4 Correlated Pairs

4.1 Finding the Standard Error

When we estimate price using antithetic variance reduction, we are generating estimates of the price (or delta, or gamma, etc.) in pairs. Let x_i denote the price obtained from the *i*th path actually generated, and x'_i denote the price obtained from the corresponding anti-correlated path. X_i will denote the random variable from which x_i is drawn, and X'_i will denote the random variable from which x'_i is drawn.

We have the following properties:

- 1. X_i and X'_i are not independent.
- 2. Each pair X_i, X_i' is independent of any other pair X_j, X_j' .
- 3. All of the random variables here have the same distribution.

Our estimator for the mean is

$$\hat{\mu} = \frac{1}{2N} \sum_{i=1}^{N} x_i + x_i'$$

where N is the number of pairs of values generated (so that the total number of values considered here is 2N). This remains an unbiased estimator. Its variance is given by

$$\operatorname{Var}(\hat{\mu}) = \operatorname{Var}\left(\frac{1}{2N}\sum_{i=1}^{N}X_i + X_i'\right)$$

$$= \operatorname{Var}\left(\frac{1}{N}\sum_{i=1}^{N}\frac{X_i + X_i'}{2}\right)$$
$$= \frac{1}{N^2}\operatorname{Var}\left(\sum_{i=1}^{N}\frac{X_i + X_i'}{2}\right)$$

Now, the random variables $X_i + X_i'$ are I.I.D., which gives us

$$= \frac{1}{N^2} \sum_{i=1}^{N} \operatorname{Var}\left(\frac{X_i + X_i'}{2}\right)$$
$$= \frac{1}{N} \operatorname{Var}\left(\frac{X_i + X_i'}{2}\right)$$

The square root of this is the standard error. This implies that the standard error for antithetic estimation should be calculated like so:

- 1. Make a list of the quantities $\frac{x_i + x_i'}{2}$ (no need to keep track of x_i or x_i')
- 2. Calculate the average of that list, which gives you the mean
- 3. Calculate the variance of that list and divide by its length
- 4. Take a square root of the previous step to get the standard error.

4.2 Analysis of Result

Let us now analyze the effectiveness of this method.

$$Var(\hat{\mu}) = \frac{1}{N} Var\left(\frac{X_i + X_i'}{2}\right)$$
$$= \frac{1}{4N} Var(X_i + X_i')$$

 X_i and X_i' are not independent. Therefore,

$$\operatorname{Var}(\hat{\mu}) = \frac{1}{4N} \left(\operatorname{Var}(X_i) + \operatorname{Var}(X_i') + 2\operatorname{Cov}(X_i, X_i') \right)$$

 X_i and X'_i are identically distributed, so their variances are equal. Thus,

$$\operatorname{Var}(\hat{\mu}) = \frac{1}{4N} \left(2\operatorname{Var}(X_i) + 2\operatorname{Cov}(X_i, X_i') \right)$$
$$= \frac{1}{2N} \left(\operatorname{Var}(X_i) + \operatorname{Cov}(X_i, X_i') \right)$$

(And we get the standard error by taking the square root of this.)

Now, we can be confident that our covariance is negative. If one member of our pair is high, we would strongly suspect that the other is low. That makes antithetic variance reduction powerful. Not only do we get to divide the variance by 2N, we also get to subtract a bit off it first. Antithetic variance reduction as presented in class on N pairs of prices actually results in a lower standard error than straight random sampling on 2N data points!

For example, if X_i and X_i' are prices generated with the inputs S = 50, K = 50, r = 0.05, $\sigma = 0.4$ and T = 1, it happens that $Cov(X_i, X_i') \approx -\frac{1}{4}Var(X_i)$. (Note: this covariance will vary depending on the inputs). If we generate N pairs, we will get

$$\operatorname{Var}(\hat{\mu}) \approx \frac{3}{8} \frac{\operatorname{Var}(X_i)}{N}$$

$$\operatorname{Var}(\hat{\mu}_{antithetic}) \approx \frac{3}{8} \operatorname{Var}(\hat{\mu}_{normal})$$

For these particular inputs, we would therefore need only 3/8 as many random numbers generated in the antithetic case compared to the usual case in order to match standard errors. To put it another way, if we generate 1,000,000 pairs via the antithetic method, we'd need roughly 2,700,000 simulations by the usual method to get the same standard error.
